AGEOS Monazit-(Ce) v hercýnskych granitoch a pegmatitoch bratislavského masívu (Západné Karpaty): variácie chemického zloženia a Th-U-Pb datovanie pomocou elektrónovej mikroanalýzy

Abstract: Monazite-(Ce) represents a characteristic magmatic accessory mineral of the Hercynian peraluminous S-type granites to granodiorites and related granitic pegmatites of the Bratislava Granitic Massif (BGM), Malé Karpaty Mountains, Central Western Carpathians, SW Slovakia. Monazite forms euhedral to subhedral crystals, up to 200 µm in size, usually it is unzoned in BSE, rarely it reveals oscillatory or sector zoning. Thorium concentrations of 2 to 9 wt. % ThO₂ (≤ 0.09 apfu) and local elevated uranium contents (≤ 4.3 wt. % UO₂, ≤ 0.04 apfu) are characteristic for the pegmatite monazites. Both huttonite ThSiREE₁P₁ and cheralite Ca(Th,U)REE₂ substitutions took place in the studied monazite. Electron-microprobe Th-U-Pb monazite dating of the granites and pegmatites gave an isochron age of 353 ± 2 Ma (MSWD = 0.88, n = 290), which confirmed the meso-Hercynian, Lower Carboniferous (Mississippian) magmatic crystallization. An analogous age (359 ± 11 Ma) was obtained from monazite from adjacent paragneiss, corresponding to the age of the Hercynian contact thermal metamorphism related to the granite intrusion of BGM. Monazite in some granite shows also older clastic or authigenic grains or zones (~ 505 to 400 Ma, with maximum of 420 ± 7 Ma) which probably represents inherited material from the Lower Paleozoic metapelitic to metapsammitic protolith of BGM.

Key words: monazite-(Ce), Th-U-Pb EMP dating, Lower Carboniferous, granitic rocks, pegmatites, Bratislava Granitic Massif, Western Carpathians

1. INTRODUCTION

Accessory monazites are essential carriers of REE in common granitic and metamorphic rocks (together with allanite, apatite, xenotime, and zircon), and their detailed study of composition and breakdown processes represent important tools for understanding the petrogenesis and evolution of the parental rock (e.g., Montel, 1993; Bea, 1996; Bingen et al., 1996; Finger et al., 1998; Broska & Siman, 1998; Förster, 1998; Zhu & O'Nions, 1999; Johan & Johan, 2005; Finger & Krenn, 2007; Krenn & Finger, 2007; Petrik & Konečný, 2009; Ondrejka et al., 2007, 2012, among many others). The presence of U, Th, and radiogenic Pb as well the almost total absence of common Pb in monazite enable us to date the mineral's crystallization or alteration by the chemical, electron-microprobe method (e.g., Suzuki et al., 1991; Montel et al., 1996; Scherrer et al., 2000; Cocherie & Albaredo, 2001; Williams et al., 2006).

Monazite-(Ce) is a widespread accessory mineral and essential REE-bearing phase in the Bratislava Granitic Massif (BGM), Slovakia. Investigations of accessory minerals revealed

a systematic presence of monazite in the BGM (Mišík, 1955; Veselský, 1972; Veselský & Gbelský, 1978) and their affinity to the monazite-series of granitic rocks (Broska & Uher, 1991). Field, K-Ar, and Rb-Sr isotopic data showed mainly Hercynian, Lower Carboniferous ages of the BGM (Koutek & Zoubek, 1936; Cambel & Valach, 1956; Kantor, 1959, 1961; Bagdasaryan et al., 1977, 1982; Cambel et al., 1979, 1990). In addition, preliminary results of the monazite electron-microprobe dating yielded age of 355 ± 18 Ma (Finger et al., 2003) identical to a zircon SHRIMP age of 355 ± 5 Ma for the BGM (Kohút et al., 2009).

Our contribution represents the first systematic study of the chemical composition and electron-microprobe dating based on a large analytical set of monazite-(Ce) analyses from the BGM, a typical example of an orogenic-related, S-type granite-pegmatite suite. The study contributes to our knowledge of the granitic protolith, the origin of monazite as a principal carrier of REE as well as the emplacement of the parental granitic rocks as an integral part of meso-Hercynian subduction to collisional events at the Gondwana frontier.

2. REGIONAL GEOLOGY

The granitic rocks forms the dominant part of the Malé Karpaty Mountains pre-Alpine basement between the towns of Bratislava and Modra, SW Slovakia (Fig. 1), as well as in a small territory of the Hundsheim Hills on the opposite side of the Danube river valley near Hainburg town, NE Austria. Two principal Hercynian granitic intrusions were emplaced in the Malé Karpaty Mts.: the Bratislava and Modra massifs.

The fundamental rock types of the BGM are muscovite-biotite monzogranites to granodiorites, less frequently there occur leucocratic two-mica to muscovite syenogranites, biotite

leucotonalites, and small bodies of biotite-amphibole diorites (Cambel & Valach, 1956; Cambel & Vilinovič, 1987; Kohút et al., 2009, and references therein). The granitic rocks are usually medium-grained equigranular, rarely porphyritic with K-feldspar phenocrysts. Systematic petrographic and geochemical studies of the BGM indicated their orogen-related, peraluminous calc-alkaline character and S-type affinity, whereas the biotite tonalites, granodiorites to granites of the Modra Granitic Massif (MGM) show I-type affinity (Cambel & Vilinovič, 1987; Petřík & Kohút, 1997; Petřík et al., 2001; Broska & Uher, 2001; Kohút et al., 2009).

Dikes of granitic pegmatites and aplites are widespread in the

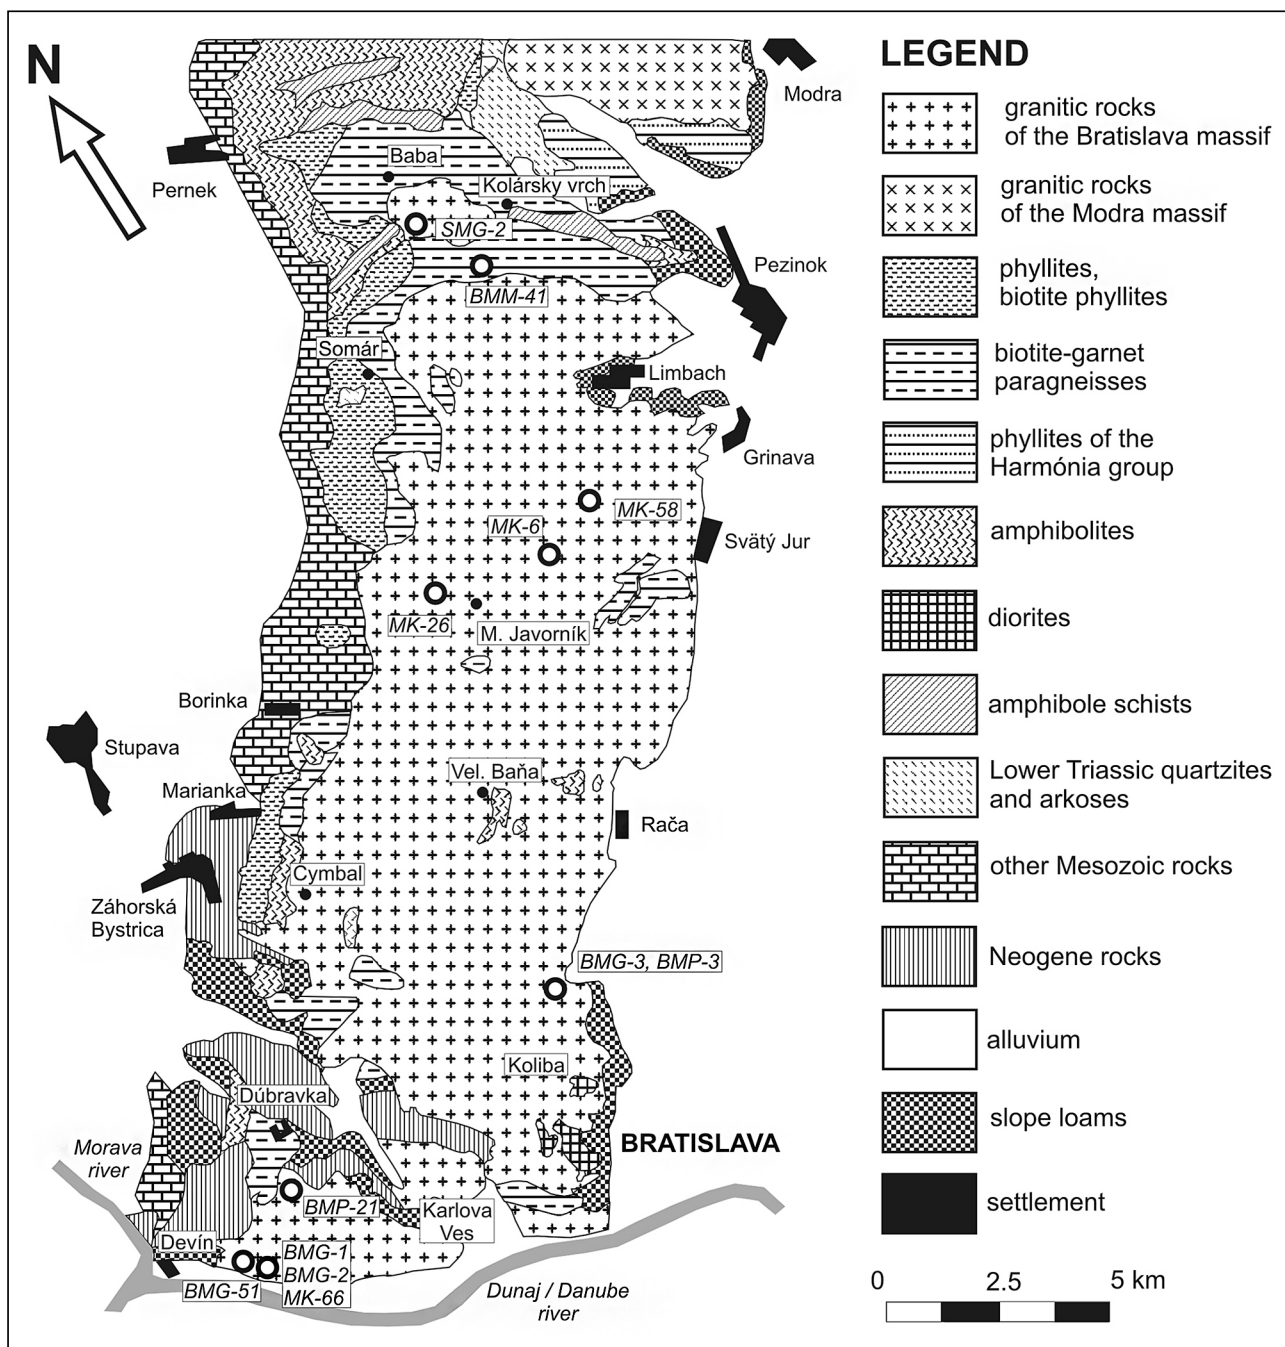

Fig. 1. Simplified geological map of the Bratislava Massif area (adapted according to Cambel & Vilinovič, 1987) with sample location.

BGM but relatively scarce in the MGM (e.g., Koutek & Zoubek, 1936; Cambel & Valach, 1956; Cambel & Vilinovič, 1987). The pegmatite dikes, usually up to 1–2 m thick, commonly show zonal structure with graphic, blocky K-feldspar, coarse-grained alkali feldspar-quartz-muscovite-(biotite) and blocky quartz core zones, locally with late fan-like muscovite and saccharoidal albite-rich replacement zones (Dávidová, 1970). The most fractionated granitic pegmatites of the BGM contain accessory beryl and Nb-Ta oxide minerals (e.g., Uher, 1994; Uher & Broska, 1995; Uher et al., 2010; Chudík et al., 2011) and they could be classified as beryl-columbite subgroup of the rare-element class of granitic pegmatites (*sensu* Černý & Ercit, 2005).

Published geological and geochronological data show Hercynian (Variscan), early Carboniferous age of the BGM and MGM intrusions and solidification (e.g., Koutek & Zoubek, 1936; Cambel & Valach, 1956; Bagdasaryan et al., 1982; Cambel et al., 1990; Finger et al., 2003; Kohút et al., 2009, see Discussion and conclusion chapter for details). The granitic rocks of the BGM and MGM exhibit distinct intrusive and thermal metamorphic contacts with adjacent metapelites to metapsammites and metabasic rocks of the Pezinok and Pernek Group (Ivan et al., 2001; Putiš et al., 2004; Ivan & Méres, 2006). The pre-metamorphic lithology of the Pezinok Group represents a relatively huge flysch sequence of pelitic and psammitic sediments, mainly rhythmically alternating sandstones and shales, locally with quartzitic, lydite, carbonate, and basaltic tuffaceous horizons, originated mainly on a continental margin (Putiš et al., 2004). Geochemical study of the Pezinok Group revealed a presence of immature greywacke rocks derived from the active continental margin near ensialic island arc with acid to intermediate magmatic rocks and the whole rock sequence represents a remnant of the back-arc rift basin filling (Ivan et al., 2001; Méres, 2005; Ivan & Méres, 2006). On the other hand, the Pernek Group represents an ophiolite sequence of metamorphosed basalts, gabbros, and pelagic pelitic rocks enriched in organic carbon substance with stratiform pyrite-pyrrhotite layers, a remnant of oceanic crust (Ivan et al., 2001; Putiš et al., 2004; Méres, 2005; Ivan & Méres, 2006). Rare microfossil remnants indicate the late Silurian, Devonian to early Carboniferous age of both the Pezinok and Pernek Group (Čorná, 1968; Cambel & Čorná, 1974; Cambel & Planderová, 1985).

The Hercynian contact thermal metamorphism of the Pezinok and Pernek groups due to intrusion of the BGM and MGM attains typical conditions of the amphibolite facies. The metamorphic conditions of the Pezinok Group due to the intrusion of the BGM were estimated at temperature up to 500–580°C and pressure of 3 to 3.5 kbar (Korikovskiy et al., 1984; Korikovskiy in Krist et al., 1992). However, thermodynamic modelling and geothermobarometric calculations show higher metamorphic conditions: $T \sim 550$ to 620°C and $P \sim 5$ to 7 kbar for staurolite-sillimanite and staurolite-garnet-bearing metapelites (Cambel et al., 1981; Dyda, 1997, 2000; Vojtko et al., 2011^{a,b}). The following metamorphic zones were developed in the metapelites to metapsammites of the contact thermal metamorphic aureole of the Pezinok Group: biotite, garnet, staurolite-chlorite, and staurolite-sillimanite zone (Korikovskiy et al., 1984; Korikovskiy in Krist et al., 1992).

3. EXPERIMENTAL METHODS

Monazites were analysed using Cameca SX-100 microprobe at the Department of the Electron Microanalysis, State Geological Institute of Dionýz Štúr, Bratislava. Monazite dating requires special measurement conditions since the calculated age strongly depends on the precise measurement of Pb, U, Th, and Y. We are using 15 kV accelerating voltage, 100 nA beam current and variable counting times depending on the measured element, Pb 150 s, Th 45 s, U 75 s, Y 45 s and all other elements 25–35 s. The elements are calibrated using synthetic or natural standards: all 14 REE elements were calibrated from synthetic phosphates, P was calibrated from apatite, Ca and Si from wollastonite, Al from corundum, Pb from galena, Th from ThO₂, and U from UO₂. Thorium, U, Pb, Y, and P were measured with LPET (large PET), and REE with LLIF (large LIF) and Si, Al with TAP analyzing crystal. The beam diameter was typically 3–5 μm. These conditions represent a suitable compromise between the degree of devastation of the measured spot, reaching high enough counting rates and the stability of the absorbed current.

The measurement is complicated by the presence of various interferences among the X-ray lines. We are using ThMα₁, UMβ₁, PbMα₁, and YLα X-ray lines. The interferences between PbMα₁ – YLγ₁ and UMα₁ – ThMβ₁ were corrected by empirically measured correction coefficients. Interferences between REE X-ray lines were also corrected, but these have no impact on the monazite dating. The fundamental requirements for monazite dating are very precise measurements of Pb, Th, U, and Y. The accuracy of monazite dating is therefore related to the monazite standards, whose variability is constrained by SHRIMP analyses. We are using the following age monazite standards: granite from Veikola, Finland (1825 Ma), pegmatite from Madagascar (495 Ma), gneiss-migmatite from Dürstein/Wachau, Austria (341 Ma), granite from Aalfang, Austria (327 Ma) and monzogranite from Nakane, Japan (77 Ma). Before measuring monazites of unknown age we first measure all age monazite standards, each at least with 20 points. The ± 5–7 Ma deviations from the age for the each monazite age standards are considered as a good precision.

The statistical approach of Montel et al. (1996) was applied for the resulting age determination. The DAMON program was used for the age recalculations, histograms, and isochron plots (Konečný et al. 2004).

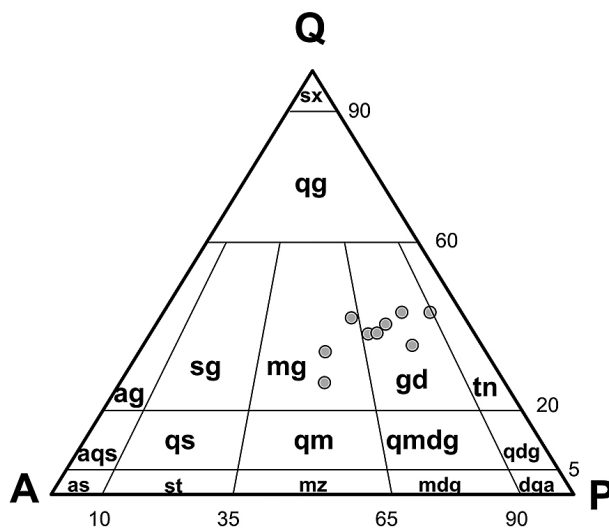

4. RESULTS

4.1. Parental rocks and monazite occurrences

Studied parental biotite granodiorites to muscovite-biotite monzogranites (Table 1, Fig. 2) show equigranular granitic, locally slightly porphyric texture. Plagioclase is the most common rock-forming mineral; it forms subhedral to euhedral crystals with polysynthetic albite-twinning, partly replaced by fine-lamellar muscovite (“sericite”), locally with albite rims. K-feldspar occurs as anhedral to euhedral crystals, with large porphyric individuals showing microperthitic or polysynthetic microcline lamellae

**Fig. 2.** QAP diagram of the studied granodiorites (gd) and monzogranites (mg) of the Bratislava Massif (vol.%).

patterns in some places. Euhedral plagioclase, rarely also biotite and quartz inclusions were identified in the K-feldspar. Quartz shows anhedral grains with undulatory extinction in association with the feldspars and micas; locally euhedral hexagonal crystals as inclusions in large K-feldspar phenocrysts were described (BMG-2 biotite monzogranite, Devín quarry). Biotite forms subhedral platy crystals in association with quartz, feldspar and muscovite or as euhedral pseudo-hexagonal crystal inclusions in K-feldspar phenocrysts. Subhedral muscovite forms late-magmatic inclusions in plagioclase; interstitial crystals or it partly replaced primary biotite. Accessory minerals include garnet (almandine > spessartine s.s.), apatite, zircon, monazite-(Ce), rarely xenotime-(Y), and opaque minerals (mainly ilmenite, magnetite, rutile, and pyrite).

Both granitic pegmatites samples (BMP-3 and BMP-21 samples) represent coarse-grained to blocky microcline-albite-quartz

assemblages with muscovite, annite, accessory beryl, almandine-spessartine, zircon, monazite-(Ce), and occasionally gahnite (BMP-21).

For comparison to monazite from the granites and pegmatites, one sample of adjacent metapelite-metapsammite rock of the Pezinok Group was also studied. The garnet-(staurolite)-bearing chlorite-biotite paragneiss (the BMM-41 sample) shows a typical lepidogranoblastic texture with quartz-plagioclase- and biotite-rich parallel bands and porphyroblasts of almandine, rarely poikilitic staurolite (up to 15 mm) and presence of magnesian chlorite (clinocllore), muscovite and accessory ilmenite, zircon, apatite, and monazite-(Ce).

4.2. Monazite zoning and composition

Monazite forms scattered euhedral to subhedral crystals, usually 10 to 200 μm across, associating with quartz, feldspars, biotite, and zircon, usually in their interstices (Fig. 3A-B). The BSE images and EMPA of the granitic rocks show a relatively homogeneous pattern of monazite without distinct internal zoning (Fig. 3-D). By contrast, monazites from the Rössler quarry pegmatites and locally also from the paragneiss reveal a sector zoning caused by Th,U,Si,(Ca)- versus REE,Y,P-enriched and depleted sectors/zones, respectively (Fig. 3E-G).

Monazite-(Ce) crystals show compositions with $\text{Ce} > \text{La} > \text{Nd} \gg \text{Sm}, \text{Y}, \text{HREE}$, exceptionally $\text{Ce} > \text{Nd} > \text{La} \gg \text{Sm}, \text{Y}, \text{HREE}$ abundances for all investigated samples (Table 2) and distinctive negative Eu anomaly in a chondrite-normalized diagram (Fig. 4). Both huttonite $\text{ThSiREE}_{1.1}\text{P}_{1.1}$ and cheralite CaThREE_2 substitutions are recorded. The huttonite substitution is important in monazite of the granitic rocks, especially from the Devín quarry, whereas cheralite substitution is characteristic in both pegmatite samples (Rössler quarry and Dúbravka) and paragneiss from Limbach (Fig. 5A-C, 6). Some monazite crystals from the BGM granites show zones enriched in Th (up to ~9 wt. % ThO_2 ; ~0.09 apfu), whereas monazite from

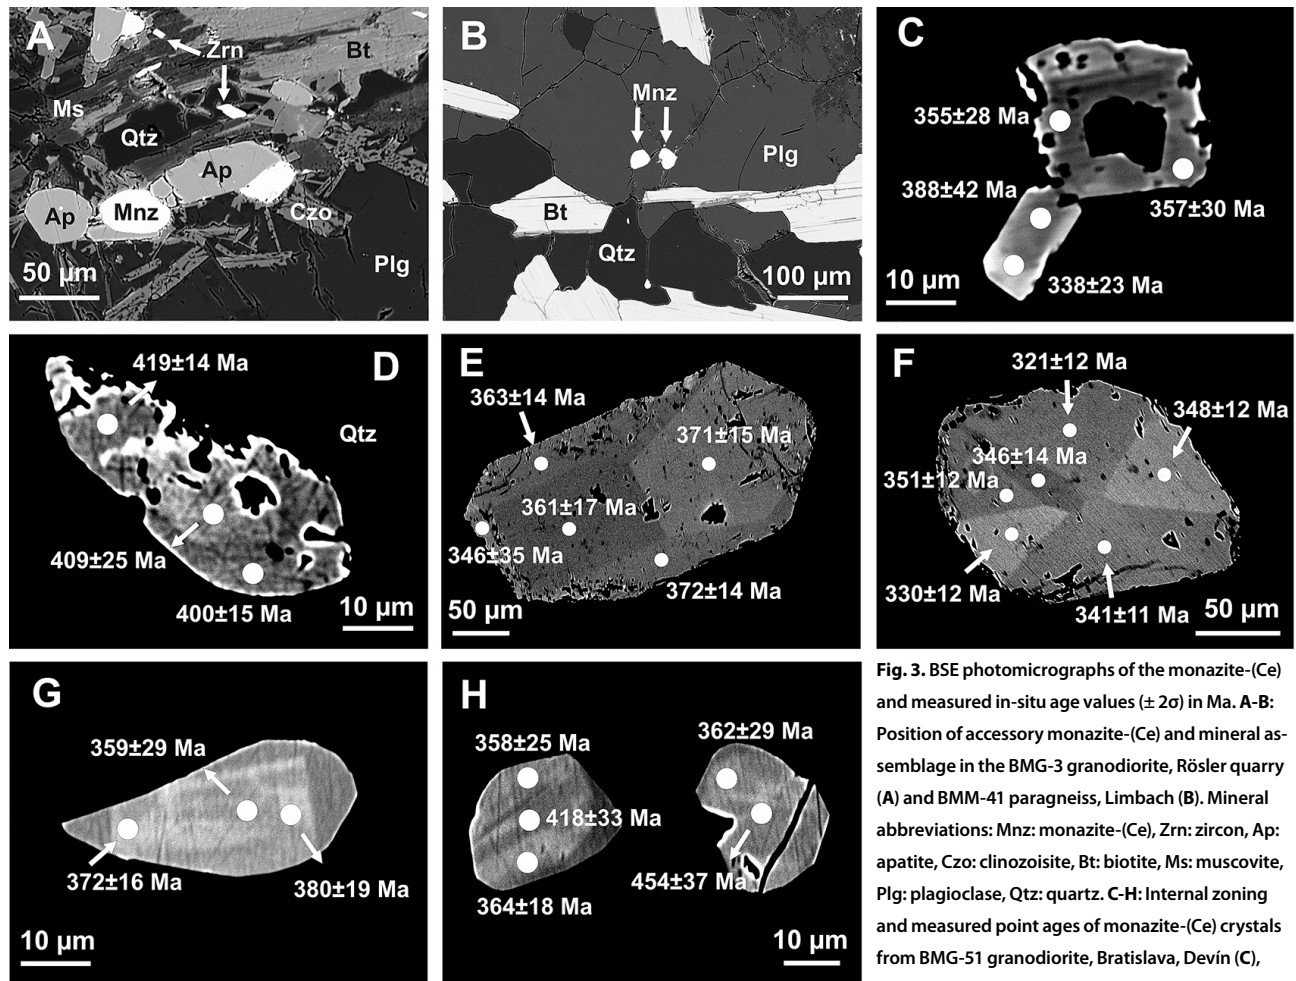

Fig. 3. BSE photomicrographs of the monazite-(Ce) and measured in-situ age values ($\pm 2\sigma$) in Ma. A-B: Position of accessory monazite-(Ce) and mineral assemblage in the BMG-3 granodiorite, Rössler quarry (A) and BMM-41 paragneiss, Limbach (B). Mineral abbreviations: Mnz: monazite-(Ce), Zrn: zircon, Ap: apatite, Czo: clinozoisite, Bt: biotite, Ms: muscovite, Plg: plagioclase, Qtz: quartz. C-H: Internal zoning and measured point ages of monazite-(Ce) crystals from BMG-51 granodiorite, Bratislava, Devin (C), SMG-2 granodiorite, Pezinok, Staré Mesto (D), BMP-3 granitic pegmatite, Bratislava, Rössler quarry (E, F), and BMM-41 paragneiss, Limbach, Slnčné Valley (G, H).

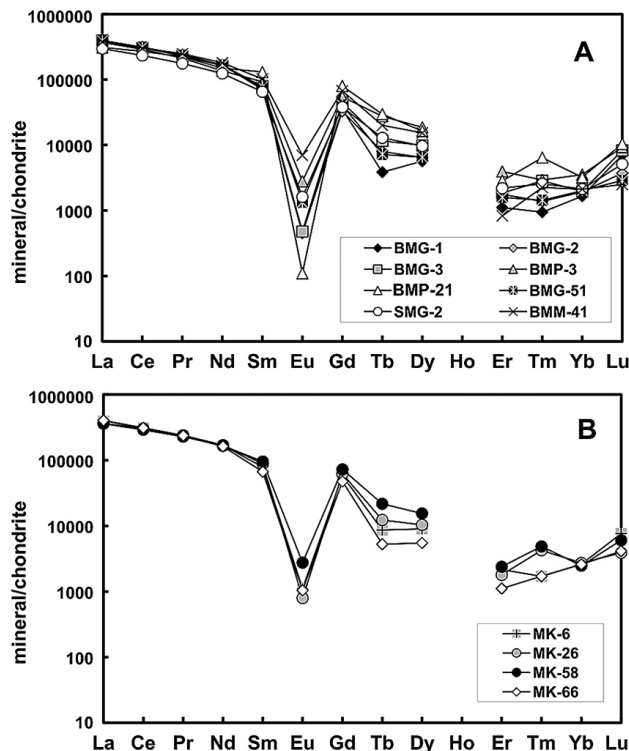

Fig. 4. A-B: Chondrite-normalized diagrams of monazite-(Ce) from the Bratislava Massif.

granitic pegmatites are commonly rich in U (up to ~ 4 wt. % UO_2 ; ~ 0.04 apfu); Table 2.

4.3. Monazite age

The investigated samples of the BGM and adjacent paragneiss gave two principal age populations: (i) dominant Hercynian, Lower Mississippian or Tournaisian ages (~ 360 to 350 Ma), and (ii) pre-Hercynian, Cambrian to Middle Devonian ages (~ 510 to 390 Ma), Table 3. The Hercynian age population displays a relatively narrow age interval for the granitic rocks and pegmatites: 359 ± 9 to 346 ± 10 Ma (Table 4). The same age is also revealed also by the staurolite-bearing paragneiss (359 ± 11 Ma). The measured Hercynian isochron ages of granites and pegmatites, (without the BMM-41 paragneiss sample) gave an average age of 353 ± 2 Ma (MSWD = 0.88, n = 290) – Table 4, Fig. 7A-B.

The older, pre-Hercynian ages in studied samples from monazite of the BGM granites and paragneiss show distribution intervals at 420–400 Ma (n = 20), 470–430 Ma (n = 13),

Bratislava Massif: Average of Pre-Hercynian ages			420	7	45	1.05

and 500–490 Ma ($n = 2$), Fig. 8A. Younger data are very rare (~ 290 to 240 Ma, $n = 5$). The pre-Hercynian ages are irregularly distributed in some monazite crystals or their zones (Fig. 3D). They are generally scarce in majority of studied granitic rocks with an exception of the SMG-2 biotite granodiorite (Pezinok, Staré Mesto), where 37 % of measured spots gave ~ 400 Ma ages (Table 3, Fig. 3D). An average calculated isochron age of the pre-Hercynian monazite population gave 420 ± 7 Ma (Table 4, Fig. 8B). A detailed comparative study of the electron-microprobe analyses revealed some compositional differences between the dominant ~ 350 Ma and the older monazite populations. Generally, the ~ 460 to ~ 400 Ma old monazite populations have commonly higher REE + Y + P + As and lower Th + U + Si contents, whereas the oldest ~ 505 to ~ 480 Ma population exhibits

usually higher Th + U + Si and lower REE + Y + P + As contents in comparison to the ~ 350 Ma one (Table 2, Fig. 5C). The composition of the youngest, ~ 290 – 240 Ma old monazite population does not show any systematic differences in comparison to both the Hercynian and pre-Hercynian populations (Fig. 5C).

5. DISCUSSION AND CONCLUSIONS

5.1. Monazite composition

Accessory monazite is one of the main carriers of the rare-earth elements (REE) in granitic rocks, together with allanite-(Ce), and xenotime-(Y). Primary magmatic monazite-(Ce) is the

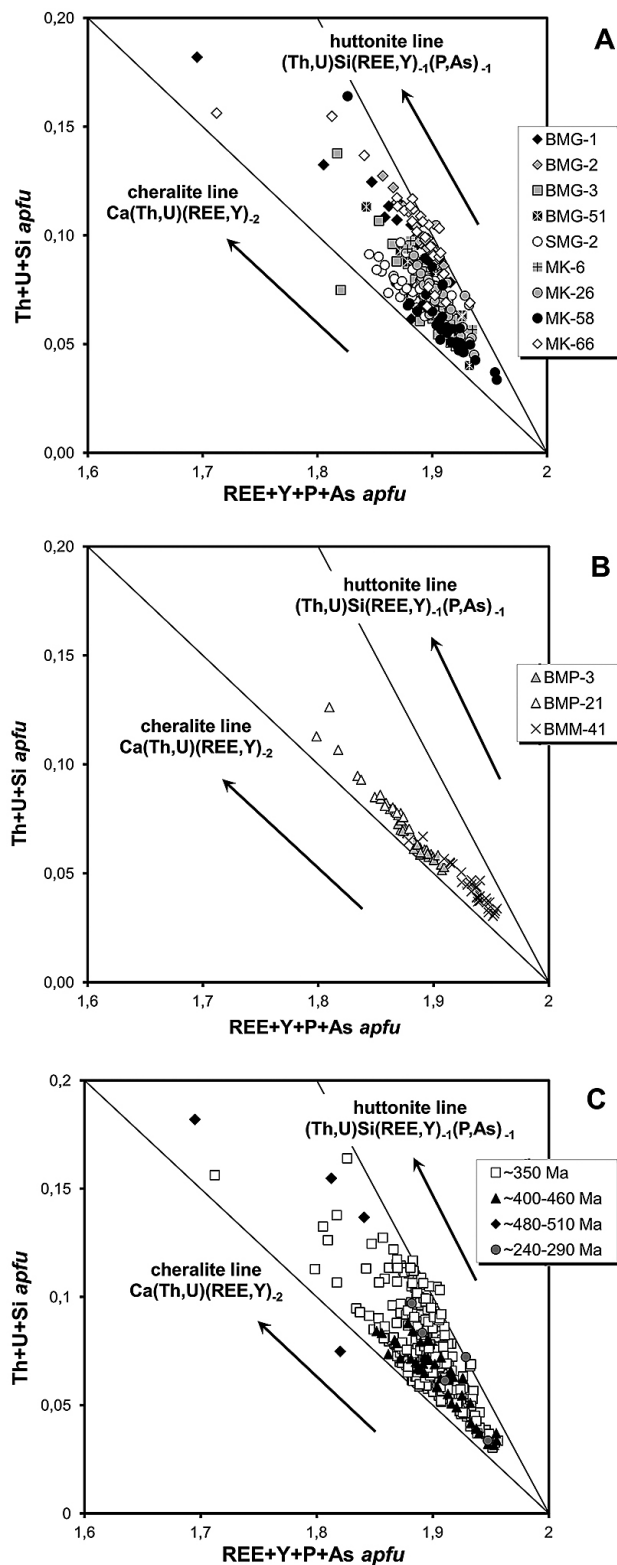

Fig. 5. Substitution Th+U+Si vs. REE+Y+P+As diagrams of monazite-(Ce) from the Bratislava Massif. A: granitic rocks, B: pegmatites and paragneiss, C: from different age populations.

most stable REE-rich phase of peraluminous (often garnet-bearing) and low-Ca, collision-related granitic suites, commonly with S-type or highly evolved I-type affiliation (e.g.,

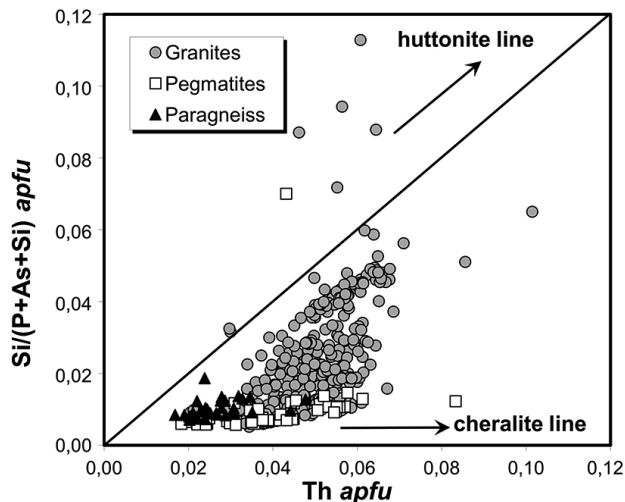

Fig. 6. Si/(P+As+Si) vs. Th diagram of monazite-(Ce) from studied granites, pegmatites and paragneiss of the Bratislava Massif. The positions of the analyses above huttonite line are probably due to microinclusions of quartz in monazite.

Broska & Uher, 1991; Bea, 1996; Förster, 1998; Kelts et al., 2008; Petřík & Konečný, 2009).

Monazite from the BGM granitic rocks are locally enriched in Th (≤ 9 wt. % ThO_2), whereas monazite from the pegmatites (especially from Bratislava, Rössler quarry) show uranium-rich zones (≤ 4 wt. % UO_2). Both huttonite $\text{ThSiREE}_{.1}\text{P}_{.1}$ and cheralite CaThREE_2 substitutions control the entry of Th and U into the monazite structure. Both the huttonite and cheralite substitutions are observed in monazite of the BGM granitic rocks, whereas cheralite substitution is dominant in both pegmatite samples and the paragneiss (Fig. 5). The increasing of Si and huttonite (ThSiO_4) molecule in monazite from granite-pegmatite systems is believed to be proportionally to higher temperatures (Broska et al., 2000). On the other hand, monazite formed at lower-temperature, more evolved and volatile-rich granites and granitic pegmatites commonly shows high Th and U contents due to enrichment in cheralite ($\text{Ca}_{0.5}\text{Th}_{0.5}\text{PO}_4$) and $\text{Ca}_{0.5}\text{U}_{0.5}\text{PO}_4$ molecules (Gramaccioli & Segalstad, 1978; Bea, 1996; Förster, 1998; Pérez-Soba et al., 2014; Uher et al., 2014). However, some monazite-huttonite s.s. from granitic pegmatites reveal anomalously high Si contents (up to 13.5 wt. % SiO_2 ; Kucha, 1980; Popova & Churin, 2010). Therefore, the behaviour of Th and U in natural monazites is complex and not unambiguous (e.g., Catlos, 2013).

5.2. Age of Bratislava Massif

The age of the BGM based on field geological relationships has been ambiguous in historical context; Richarz (1908) assumed the Alpine, post-Liassic age on the basis of wrong observations of the granite-related contact metamorphic overprint on Mesozoic (Liassic) limestones in the Hainburg castle hill. However, other authors suggested the Hercynian (Variscan) age (e.g., Koutek

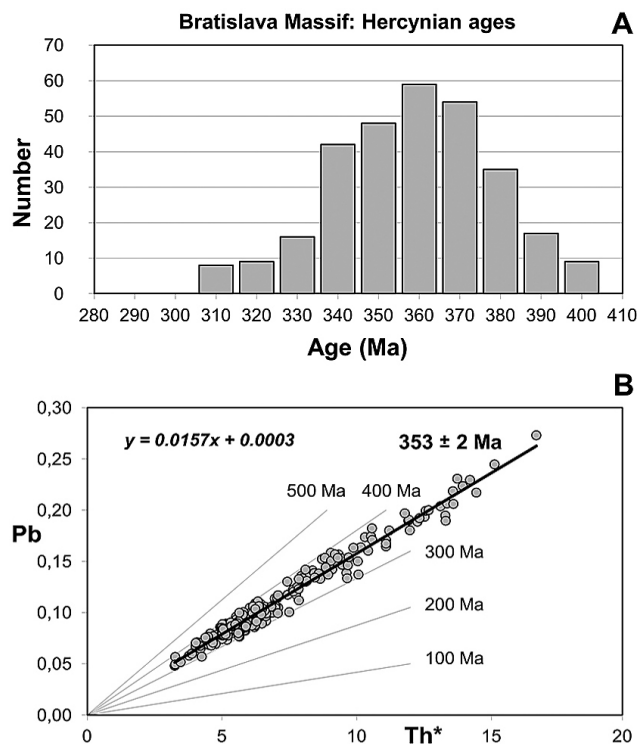

Fig. 7. Histogram (A) and isochron diagram (B) of Hercynian monazite-(Ce) ages from the studied granitic rocks and pegmatites of the Bratislava Massif. Pb values are in wt. %, $Th^* = Th + 3.15 \cdot U$ wt. %.

& Zoubek, 1936), confirmed by findings of analogous granitic rocks as pebbles in the Permian (?) to Lower Triassic arkoses to quartzites (Cambel & Valach, 1956).

The first K-Ar isotopic geochronological data of K-feldspar and micas from BGM also indicated mainly the Upper Paleozoic, Hercynian ages (Kantor, 1959, 1961; Bagdasaryan et al., 1977). Later, Rb-Sr dating confirmed the Hercynian age of BGM with a 347 ± 4 Ma whole-rock isochron (Bagdasaryan et al., 1982), whereas biotite-whole rock and especially biotite-muscovite Rb-Sr isochrons indicated generally younger ages (Cambel et al., 1979, 1990; Bagdasaryan et al., 1982). Preliminary results of Th-U-Pb electron-microprobe monazite dating of BGM revealed the Lower Carboniferous, Hercynian age (355 ± 18 Ma, Finger et al., 2003). Recently, the Hercynian, 355 ± 5 Ma age of BGM has been confirmed also by zircon U-Th-Pb SHRIMP dating (Kohút et al., 2009).

Consequently, there is no more doubt of the Hercynian age of magmatic solidification. However, the K-Ar ages from BGM show a large variation (379 to 233 Ma) due to released internal fluids during rapid cooling and/or the partial Alpine overprint. Similarly, whole-rock – mineral (biotite, muscovite) Rb-Sr isochrons (279 to 159 Ma) indicate post-crystallisation opening of system or alteration, although whole-rock isochron gave a rather reasonable age 347 ± 4 Ma from the magmatic crystallisation point of view (Bagdasaryan et al., 1982). Our robust result (353 ± 2 Ma) based on 290 spot dating measurements is thus in excellent accordance with published monazite age from this massif 355 ± 18 Ma (Finger et al., 2003) done from limited

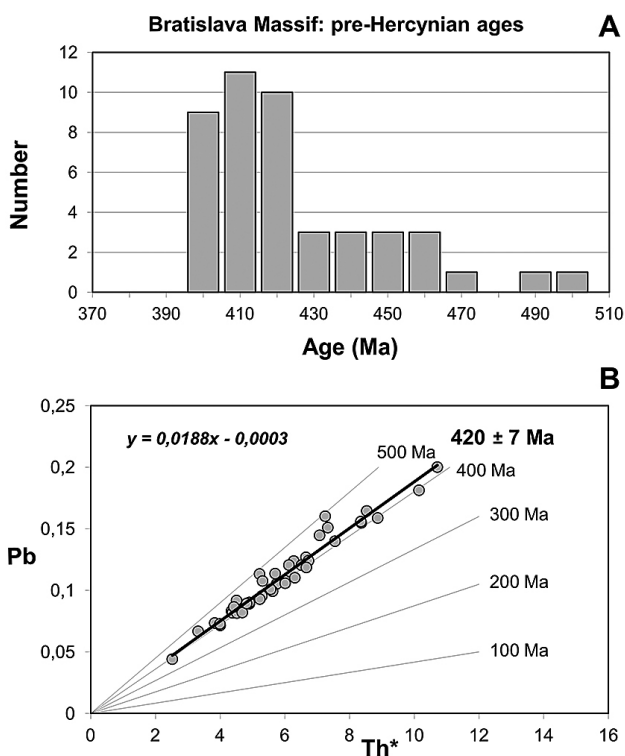

Fig. 8. Histogram (A) and isochron diagram (B) of pre-Hercynian monazite-(Ce) ages from the studied granitic rocks of the Bratislava Massif. Pb values are in wt. %, $Th^* = Th + 3.15 \cdot U$ wt. %.

spot measurements ($n = 10$), as well as SHRIMP zircon dating (355 ± 5 Ma, Kohút et al., 2009).

The age of the inherited monazite population, locally preserved in monazite crystals from some granitic rocks of BGM show a relatively wide interval of ~505 to 400 Ma, with an average calculated isochron age of 420 ± 7 Ma (Table 4, Fig. 8B), which corresponds to the Silurian–Devonian boundary (International chronostratigraphic chart, version 2014/02). These pre-Hercynian ages probably indicate a presence of older clastic monazite grains and/or low-temperature authigenic to metamorphic monazite inherited from pelitic to psammitic metasedimentary rocks, a main protolith of the S-type granites of the BGM. Moreover, the main population of the older, pre-intrusion monazite ages (420–400 Ma) roughly corresponds to age of the first, regional metamorphic overprint of the metapelites to metapsammites around the BGM under the greenschist facies, as revealed by Rb-Sr isochron dating (387 ± 38 Ma – Bagdasaryan et al., 1983; 380 ± 20 Ma – Cambel et al., 1990).

5.3. Meso-Hercynian granitic plutonism of the Western Carpathians and geodynamic implications

The Lower Carboniferous (Mississippian) age of $\sim 350 \pm 10$ Ma represents the dominant magmatic event for the origin of S- and I-type granitic rocks in the West-Carpathian Hercynian Belt (WCHB). The dominance of the $\sim 350 \pm 10$ Ma magmatism in the WCHB is documented by numerous U-Pb zircon ages from the Tatic Unit, e.g., the Malá Fatra Mountains: 353 ± 11 Ma

(Scherbak et al., 1990), the Veľká Fatra Mts.: 356 ± 25 Ma (Kohút et al., 1997), the Strážovské Vrchy Mts.: 356 ± 9 Ma (Kráľ et al., 1997), the Tatry Mts.: 347 ± 14 Ma to 357 ± 7 Ma (Poller et al., 2000, 2001) and 350 ± 5 Ma (Burda et al., 2013), the Nízke Tatry Mts.: $353\text{--}356 \pm 3$ Ma (Broska et al., 2013); as well as from the Veporic Unit: the Sinec type: 350 ± 5 Ma (Bibikova et al., 1988), the Kráľova Hoľa type: 345 ± 11 Ma (Gaab et al., 2005), and the Sihla type: 357 ± 2 Ma (Broska et al., 2013). Isochrone Rb-Sr and electron-microprobe Th-U-Pb monazite dating of the West-Carpathian Hercynian granitic suites yields commonly analogous ages (e.g., Bagdasaryan et al., 1982, 1990; Cambel et al., 1990; Finger et al., 2003, and references therein). Moreover, the Hercynian metamorphic overprint of older, probably the Ordovician orthogneisses in the Nízke Tatry and Vepor Mts., gave an analogous, 340–350 Ma age interval by monazite chemical dating (Petrík et al., 2006; Ondrejka et al., 2012). In-situ SHRIMP zircon U-Th-Pb dating from I-type granitic suites also revealed an age interval of 347 ± 4 Ma for the Modra Granitic Massif (Kohút et al., 2009). Moreover, slightly older, the Devonian to Mississippian ages (~360 to 370 Ma) were determined for the anatectic migmatites of the Western Tatra Mts.: 359 ± 1 to 365 ± 2 Ma (Burda, 2007) and 368 ± 8 Ma (Burda et al., 2011) and granites of the Tribeč Mts.: 358 to 367 ± 3 Ma (Broska et al., 2013).

The geodynamic evolution of the WCHB is generally comparable to the Variscan (Hercynian) orogenic belt of western and central Europe, mainly in the Massif Central and the Bohemian Massif, where dominant I-type granitic rocks emplaced during ~360 to 350 Ma period, e.g., in the Central Bohemian Granitic Belt (Finger et al., 2009; Janoušek et al., 2004, 2010). A similar evolution was suggested for crystalline basement of the Alpine-Carpathian realm (e.g., Franke, 1992; von Raumer & Neubauer, 1993; Stampfli, 1996; Plašienka et al., 1997; Petrík & Kohút, 1997; Broska et al., 2013). Generally, the collision of two major continental plates: Gondwana and Baltica (Laurasia), caused the closure of Paleotethys ocean, subsequent collision of minor continental fragments evolved from the disruption of the northern margin of Gondwana (including the Galatian superterrane, where probably an original area of WCHB was situated), and initiated partial melting, intrusion and emplacement of the meso-Hercynian granitic suites in the Western Carpathians (Broska et al., 2013).

Appendix: Sample location

 For U-Th-Pb electron-microprobe monazite dating the following samples were measured (Fig. 1):

- BMG-1:** medium-grained, equigranular biotite granodiorite. Bratislava, Devín, large active quarry, 3200 m/150° from Devínska Kobyla (altitude point 514.1 m asl.).
- BMG-2:** medium-grained, slightly porphyric biotite monzogranite. Bratislava, Devín, large active quarry, 3200 m/150° from Devínska Kobyla (altitude point 514.1 m asl.).
- BMG-3:** fine-grained, equigranular muscovite-biotite granodiorite. Bratislava, abandoned Rössler quarry, 1950 m/90° from Kamzík (altitude point 439.4 m asl.).
- BMP-3:** granitic pegmatite dike in BMG-3 granodiorite, coarse-grained K-feldspar–albite–quartz–biotite–muscovite zone. Bratislava, abandoned Rössler quarry, 1950 m/90° from Kamzík (altitude point 439.4 m asl.).
- BMP-21:** granitic pegmatite dike in granitic rocks. Bratislava, Dúbravka, natural outcrop, 450 m/75° from Švábsky vrch (altitude point 359.8 m asl.).
- BMG-51:** medium-grained, porphyric muscovite-biotite granodiorite. Bratislava, Devín, natural outcrop ca. 500 m SE of Devín village, 2500 m/180° from Devínska Kobyla (altitude point 514.1 m asl.).
- SMG-2:** medium-grained, equigranular biotite granodiorite. Pezinok, old dumps of the Staré Mesto gold deposit, 1300 m/105° from Konské Hlavy (altitude point 648.8 m asl.).
- MK-6:** fine-grained, equigranular muscovite-biotite granodiorite. Bratislava, Rača, small natural outcrop, 150 m/260° from Veľký Javorník (altitude point 593.7 m asl.).
- MK-26:** fine- to medium-grained, equigranular muscovite-biotite monzogranite. Borinka, Popálené, small natural outcrop, 1150 m/295° from Malý Javorník (altitude point 583.7 m asl.).
- MK-58:** medium-grained, slightly porphyric, muscovite-biotite monzogranite. Svätý Jur, Človečia Hlava, small natural outcrop, 1450 m/65° from Veľký Javorník (altitude point 593.7 m asl.).
- MK-66:** medium-grained, slightly porphyric biotite granodiorite. Bratislava, Devín, large active quarry, 3200 m/150° from Devínska Kobyla (altitude point 514.1 m asl.).
- BMM-41:** Biotite paragneiss with chlorite, garnet and staurolite. Limbach, Slnčné Valley, natural outcrop, 900 m/210° from Žilová Hill (altitude point 447.5 m asl.).
